METHOD AND SYSTEM FOR LOCATING
A GPS CORRELATED PEAK SIGNAL

Background of the Invention

1.   Technical Field

The present invention relates generally to a global positioning system

(GPS), in particular, a receiver for use in a GPS and a method thereof.

2.   Discussion of Related Art

A Global Positioning System (GPS) receiver determines its position by

computing the distance from and relative times of arrival of signals transmitted

simultaneously from a number of GPS satellites.   These satellites transmit, as

part of their message, both satellite positioning data including pseudo-random

codes as well as data on clock timing.

Using the received pseudo-random codes, the GPS receiver determine

pseudoranges to the various GPS satellites, and computes the position of the

receiver using these pseudoranges and satellite timing and data on clock timing.

The pseudoranges are time delay values measured between the received signals

from each satellite and a local clock signal. Usually GPS signals from four or

more satellites are received.   The satellite data on clock timing and signature

data is extracted from the GPS signals once a satellite is acquired and tracked.

Acquiring GPS signals can take up to several seconds and must be accomplished with a sufficiently strong received signal to achieve low error rates.

GPS signals contain high rate repetitive signals called pseudorandom (PN) codes. The codes available for civilian applications are called C/A (coarse/acquisition) codes, and have a binary phase-reversal rate, or "chipping" rate, of 1.023 MHz and a repetition period of 1023 chips for a code period of 1 millisecond. The codes sequences belong to a family known as Gold codes, and each GPS satellite broadcasts a signal with a unique Gold code.

Most GPS receivers use correlation methods to compute pseudoranges. A correlator multiplies the received signal by a stored replica of the appropriate Gold code contained within its local memory, and then integrates the product to obtain a correlation or sampling value, which is used as indication of the presence of the satellite signal. By sequentially adjusting the relative timing of this stored replica relative to the received signal, and observing the correlation output, the receiver can determine the time delay between the received signal and a local clock. The initial determination of the presence of such an output is termed "acquisition." Once acquisition occurs, the process enters the "tracking" phase in which the timing of the local reference is adjusted in small amounts to maintain a high correlation output.

Global Position Satellite Systems utilize a multiplicity of satellites (constellation) to simultaneously transmit signals to a receiver to permit position location of the receiver by measurement of time-differences of arrival between these multiple signals. In general, the signals from the different satellites do not

significantly interfere with one another, since they utilize different pseudorandom

spreading codes that are nearly orthogonal to one another. This low interference

condition depends upon the power levels (amplitudes) of the received signals

being similar to one another.

5   To reduce acquisition time, a GPS receiver uses several channels to

handle signals that may come from several satellites. Each channel includes

multi-correlation taps for use in the correlation operations. Typically, the data

received at each correlation tap is stored in a memory. The stored data is

processed and correlated. The size of the memory is proportional to the number

10   of channels and taps. To reduce acquisition time, memory having sufficient

capacity and speed is needed. However as a memory component ratio in the

GPS receiver increases, it becomes more difficult to miniaturize the GPS receiver.

Fig. 1 shows a block diagram of a conventional GPS receiver having an

antenna 1, a down converter 2, a local oscillator 3, and an A/D converter 4,

15   receiver channels 5, a receiver processor 6, a navigation processor 7, and a user

interface 8. In operation, the antenna 1 receives signals through the air

transmitted from a constellation of satellites. The down converter 2 converts the

high frequency signal received at the antenna 1 to a lower intermediate frequency

(IF) signal by mixing the signals with a local oscillation signal generated by the

20   local oscillator 3. The A/D converter 4 converts the analog IF signals to digital

signals for processing by the receiver channels 5. The IF signals received at the

receiver channels 5 is processed by the receiver channels 5, the receiver

processor 6 and the navigation processor 7. The receiver channels 5 have N

channels and the N channels can be set by a manufacturer. The primary

functions of the receiver processor 6 include generating a plurality of

pseudoranges for each satellite and perform the correlation operation with the in-

phase (I) and quadrature-phase (Q) data of each channel. The navigation

5   processor 7 sets a position value using different pseudoranges for the different

satellites. The user interface 8 is used to display the position data.

Fig. 2 shows a block diagram of one of the N channels in receiver channel

5 of Fig. 1. The digital IF signals received from the A/D converter 4 of Fig. 1 are

fed to in-phase/quadrature-phase multipliers 10 wherein the IF signals are

10   multiplied with signals generated by in-phase sine map 11 and quadrature-phase

cosine map 12 or quadrature-phase sine map 11 and in-phase cosine map 12,

each of which is in turn generated by a Numerical Code Oscillator (NCO) 19.

The output of the in-phase/quadrature-phase multipliers 10 are in-phase IF

signals corresponding to the phase of sine map 11 and quadrature-phase IF

15   signals corresponding to the phase of cosine map 12 or the output of the in-

phase/quadrature-phase multipliers 10 are quadrature-phase IF signals

corresponding to the phase of sine map 11 and in-phase IF signals corresponding

to the phase of cosine map 12. The receiver processor 6 generates the numerical

code for controlling the NCO 19 for generating a Doppler frequency. The receiver

20   processor 6 also generates a clock control signal input to code NCO 18 for

interlocking the PN code generator 16. Pseudo-random codes associated with the

satellites are generated by the PN code generator 16. The PN codes are shifted

by code shifters 17 and output to a plurality of correlators 13. Correlation is

performed using the correlators 13 by comparing the phase shifted PN codes to the I and Q data received from the in-phase/quadrature-phase multipliers 10. The correlated I and Q data from the correlators 13 are output to an integrator 14 wherein the correlated I and Q values are integrated. The integrated values, also known as sampling values, are stored in memory 15. Typically, each channel of the N channels of receiver channels 5 stores in memory 15 all sampling values sampled by the integrator 14 for a given duration, such as 1 millisecond for each tap. Upon collection of a predetermined number of samples, the sampled values are forwarded to an FFT unit 20 wherein fast Fourier transform is performed to determine if a peak (correlation) exists for this tap. If a peak is found, the receiver processor 6 extracts the frequency and code value information from the tap to calculate pseudoranges for acquisition.

If it is determined that a peak does not exist in the sampled tap, the sampling, correlation, and FFT processing is repeated for each tap until the peak tap is located.

It can be seen from this process that a large amount of data need to be stored in the receiver memory 15. Thus, memory having sufficient capacity is needed. Further, because of the need to access memory data for processing, memory access time is an important factor affecting acquisition speed and thus performance of the receiver.

Summary of the Invention

A global positioning system (GPS) receiver is provided, comprising a converter for converting received GPS signals to in-phase (I) and quadrature-phase (Q) digital signals; a correlator for generating expected codes and correlating the I and Q digital signals with the expected codes to output sampled I values and sampled Q values for a tap; a filter for filtering the sampled I values and sampled Q values to modified I values to each of the modified Q values, and for adding each of the modified I values to each of the corresponding modified Q values of the tap, and for outputting a count for sum which is positive; a counter for incrementing a counter value upon each count received from the filter; and a comparator for comparing the counter value to a threshold value upon completion of measure of values of the tap for determining the presence of a peak.

The sampled I values and sampled Q values can be modified by assigning a positive value to the sampled I value or sampled Q value when a present sample I value or Q value has a different sign from the immediately prior sample I value or sample Q value, modified I values and modified Q values can be fractional reductions of respective sampled I values and sampled Q values, the fractional reduction being the same for both the sampled I values and the sampled Q values, wherein the fractional reduction is one half.

A memory is provided for storing sampled I and Q values of the tap found to have a counter value exceeding the threshold, wherein sampled I and Q values of other taps are not stored in the memory, a domain transformer for performing

6

domain transform on data stored in the memory. The filter includes a pair of delay elements and a pair of single bit comparators, wherein the delay elements delay a sign bit of the sampled I value and the sampled Q value to output a prior sign value, and the single bit comparators compare a sign of the present sampled Q value with the prior sign value to provide a positive output if the present and the prior sign values are different.

According to another aspect of the invention, a global positioning system (GPS) receiver is provided, comprising a converter for converting received GPS signals to in-phase (I) and quadrature-phase (Q) digital signals; a correlator for generating expected codes and correlating the I and Q digital signals with the expected codes to output sampled I values and sampled Q values for a tap; a filter for filtering the sampled I values and sampled Q values to modified I values and modified Q values, and for adding each of the modified I values to each of the corresponding modified Q values of the tap, and for outputting a count for each sum which is positive; a counter for incrementing a counter value upon each count received from the filter; a comparator for comparing the counter value to a threshold value upon completion of measure of values of the tap for determining the presence of a peak; and a memory for storing the sum of each of the modified I values and corresponding modified Q values of the tap having a counter value exceeding the threshold.

The sampled I values and sampled Q values can be modified by assigning a positive value to the sampled I value or sampled Q value when a present sample I value or Q value has a different sign from the immediately prior sample I

7

value or sample Q value. The modified I values and modified Q values can be fractional reductions of respective sampled I values and sampled Q values, the fractional reduction being the same for both the sampled I values and the sampled Q values, wherein the fractional reduction is one half.

The filter includes a pair of delay elements and a pair of single bit comparators, wherein the delay elements delay a sign bit of the sampled I value and the sampled Q value to output a prior sign value, and the single bit comparators compare a sign of the present sampled Q value with the prior sign value to provide a negative output if the present and the prior sign values are different. The memory further stores the sampled I and Q values of the tap identified as having a peak, wherein the memory is one of a SRAM or a DRAM.

A method of processing global positioning system (GPS) signals for determining position is also provided, comprising a converting received GPS signals to in-phase (I) and quadrature-phase (Q) digital signals; correlating the I and Q digital signals with the expected codes to output sampled I values and sampled Q values for a tap; filtering the sampled I values and sampled Q values to modified I values and modified Q values, adding each of the modified I values to each of the corresponding modified Q values of the tap, and outputting a count for each sum which is positive; incrementing a counter value upon each count received from the filter; and comparing the counter value to a threshold value upon completion of measure of values of the tap for determining the presence of a peak.

The sampled I values and sampled Q values can be modified by assigning

8

a positive value to the sampled I value or sampled Q value when a present sampled I value or Q value has a different sign from the immediately prior sampled I value or sampled Q value.

The modified I values and modified Q values can be fractional reductions of respective sampled I values and sampled Q values, the fractional reduction being the same for both the sampled I values and the sampled Q values, wherein the fractional reduction is one half.

The method further includes storing in a memory sampled I and Q values of the tap having a counter value exceeding the threshold, wherein sampled I and Q values of other taps are not stored in the memory, and including performing domain transform on data stored in the memory. The sum of each of the modified I values and corresponding modified Q values of the tap found to have a counter value exceeding the threshold can also be stored.

Alternatively, the memory stores the sampled I and Q values of the tap found to have a peak, wherein sampled I and Q values of taps not found to have a peak are not stored in the memory.

According to another aspect of the invention, a stored program device having stored codes executable by a processor to perform method steps for processing GPS signals is provided, the method comprising a correlating the I and Q digital signals with the expected codes to output sampled I values and sampled Q values for a tap; filtering the sampled I values and sampled Q values to modified I values and modified Q values, adding each of the modified I values to each of the corresponding modified Q values of the tap, and outputting a count for

each sum which is positive; incrementing a counter value upon each count

received from the filter; and comparing the counter value to a threshold value

upon completion of measure of values of the tap for determining the presence of a

peak.

5

Brief Description of the Drawings

The embodiments of the present invention will become more apparent

when detail description of embodiments are read with reference to the

accompanying drawings in which:

Detailed Description of Preferred Embodiments

Hereinafter, preferred embodiments of the present invention will be described in detail with reference to the accompanying drawings. It should be noted that like reference numerals are used for designation of like or equivalent parts or portion for simplicity of illustration and explanation.

Fig. 3 shows a block diagram of a GPS receiver according to an embodiment of the present invention. The components of the receiver shown in Fig. 3, other than a filter 30, perform the functions described above for the components of Fig. 2. The filter 30 is configured to receive the sampling I and Q values output from the integrator 14. According to at least one embodiment of the present invention, the filter 30 modifies the sampled I and Q values so that a data set that is reduced from the sampled values are chosen for storage in memory 15. According to another embodiment of the present invention, the filter 30 extracts the correlation characteristics of the sampled I and Q values and selectively stores the I and Q values or modified I and Q values based on a screening process. The I and Q sampling values of a tap determined to not have a peak are

discarded and they are not stored in memory. Processing of the stored data by the FFT unit 20 to determine the existence of a peak tap is more efficient because of the reduced data set and the capacity requirement of the memory 15 is also reduced, thereby reducing power consumption and the physical size of memory

5   15.

Fig. 4 shows an exemplary implementation of the filter 30 of Fig. 3. The sampled I and Q values output from integrator 14 is input to a pair of delay elements 23, 24 and sign bit comparators 25, 26. For purposes of illustrating embodiments of the present invention, the sampled I and Q values are selected to

10   be 16 bits, the duration of sampling is selected to be 1 millisecond, and each sample frame is chosen to be 16 samples. It is to be appreciated that different bit numbers, sampling durations, and sampling frame can be used without departing from the present invention. As shown in Fig. 4, each of 16 bits of data representing sampled I and Q values plus one sign bit is input to one of n-taps of

15   the filter 30. The circuit of tap 0 is shown in Fig. 4. The sign bit is input to the delay element 23 which delays for one clock period the sign bit before it is entered into the sign bit comparator 25. The sign bit comparator 25 facilitates the comparison of the sign values of the prior sampled I data with the present sampled I data. The sign bit comparator 25 outputs a logic 0, signifying a positive

20   number, if the present sign bit is different from the prior sign bit. The delay element 24 and the sign bit comparator 26 perform the above described functions for the sampled Q data. Thus, the sampled I and Q data are modified in their sign (or direction) depending on the direction of the sampling data with respect to time.

The modified I and Q data are input to an accumulator 27 wherein the modified I and Q data including their sign bits are added. The accumulated data is 'variation data'.

According to the present embodiment, the 16 variation data accumulated from the modified I and Q values are output for storage in memory 15. The stored data is then used by the FFT unit 20 to perform a Fourier transform for determining whether an actual peak exist in this tap. The sign bit comparators 25 and 26 are preferably implemented by using an exclusive nor (xnor) logic. It is to be appreciated that the sign bit comparators can also be implemented using an exclusive or (xor) logic and in such embodiment the comparison will result in a negative value (logic 1). When the present sample value and the prior sample value have same signs with using the xnor logic or when the present sample value and the prior sample value have different signs with using the xor logic, the counter 28 counts the number of logic 1. If a peak is not formed for this tap, the above described process is repeated for the next tap.

Fig. 5 shows another exemplary implementation of the filter 30 of Fig. 3 according to an alternative embodiment of the present invention. Referring to Fig. 5, whenever a negative value result from the accumulation of the modified I and Q values in the accumulator 27, a logic one signal is output to a counter 28 to increment a count for this tap. The counter 28 is reset to zero at the beginning of data sampling for each tap. Upon completion of a sampled frame, e.g. 16 samples, the final count is compared against a preset threshold in the logic circuit 29. If the count value exceeds the preset threshold, for example, 12 out of 16,

13

data from tap 0 is considered as a potential peak. In such case, the sampled I and Q values of the tap in question is stored in memory 15. The stored data is then processed by the FFT unit 20 and the receiver processor 6 to determine if a peak exists in this tap. If the count value for any particular tap does not exceed the preset threshold, the sampled I and Q values, the modified I and Q data, and the variation data are not stored in the memory 15. These data can be discarded.

Fig. 6 shows still another exemplary implementation of the filter 30 of Fig. 3 according to an alternative embodiment of the present invention. Referring to Fig. 6, upon indication of a count value exceeding the present threshold, as determined by the logic 29, the variation data output from the accumulator 27 is output to be stored in memory 15 instead of the sampled I and Q values. According to this embodiment, the variation data of a potential peak tap is stored and processed by the FFT unit 20 and the receiver processor 6. Thus, the dataset stored in memory 15 is a further reduction from the dataset of the sampled I and Q values output from the integrator 14.

Table 1 lists exemplary data received from a tap and the processing of the data by the filter 30 according to an embodiment of the present invention.

						Number of 1's	7

Table 1. The variation value generation table in the case a peak tap does not exist.

In table 1, 16 samples of sampled I and Q values output from the integrator 14 and received at the filter 30 are shown in columns I and Q. The modified I and Q values are shown in columns I' and Q', respectively. As shown therein, the sign of each sample value is assigned a positive value when there is a change in the sign between the present sample value and the prior sample value of I and Q. The I and Q values are modified by the delay element 23 and the sign comparator 25 for the sampled I values and the delay element 24 and sign comparator 26 for the Q sample values. The modified I and Q values, I' and Q', are added by accumulator 27 to output variation value. This sum is shown in Table 1 in the column labeled as Variation Value (I'+Q'). The sum operation in accumulator 27 adds the magnitude of I' and Q', taking into account the sign of both I' and Q' values. For each occurrence of a negative value output from the accumulator 27,

15

a transition is sent to the counter 28 to increment the counter value. As shown in the count value column of Table 1, the count value for the data from this tap is 7 out of a frame of 16 samples. This signifies that there were 7 negative values from the summation of the modified I' and Q' sample values. Table 1 shows data for a tap which does not have a peak.

One ordinary skilled in the art recognizes that for the existence of a peak in a tap, the sampled I and Q values will appear as two clusters, one for the sampled I values and one for the sampled Q values. Fig. 7 shows both sampled I and Q values swinging in different directions around the zero axis. One ordinary skilled in the art viewing the plot shown in Fig. 7 would recognize that the tap under question does not have a peak.

According to embodiments of the present invention and as shown in Table 1, the count value is a measure of the number of change in direction of the sampled I and Q values between the zero axis. Thus, a count of seven (7) out of sixteen (16) dataset can be construed as a dataset having data points which swing in different directions around the zero axis and are not clustered away from the zero axis. From the count value of 7 out of 16, the tap can be dismissed as one not having a peak.

Table II.

Table II shows sampled I and Q values from a tap having a peak. As can be seen from Table II, the sampled I and Q values are clustered largely in the same direction throughout the 16 samples. It can also be seen that the modified I and Q sampled values (I' and Q'), as modified by the filter shown in Fig. 4, result in modified I and Q values with a negative sign essentially throughout the 16 samples for both I' and Q' signaling little or no change in direction of the I and Q sample values. Therefore, the output of the accumulator 27 (I' + Q') result in a larger negative value that is clustered well above the zero axis. Since each variation value (I' + Q') is negative, the counter is counted 16 times to result in a count value of 16. This is recognized as a tap having a peak.

Fig. 8 shows a plot of the sampled I and Q values listed in Table II. It can

be seen that there are two clusters of data, one for the I sampled values and the other for the Q sampled values.

According to an embodiment of the present invention, to determine whether a peak existence at a particular tap, the variation values (I' + Q') are stored in memory 15, and stored variation values are processed by the FFT unit 20 to search for the existence of a peak. Existence of a peak can be determined by the variation values transformed by the FFT unit 20 when compared against a value predetermined to define the existence of a peak. When a peak is determined to be present at a tap, the frequency, code values, and phase offsets are extracted from the sampled I and Q values and pseuodoranges are calculated.

Alternatively, to further reduce the dataset, the sampled I and Q values are reduced by a fractional multiplier, such as by ½, ¼, etc. prior to its filtering and processing by the filter 30 and the FFT unit 20. The multiplier (not shown) can be part of the filter 30 or disposed between the integrator 14 and the filter 30.

Fig. 9 illustrates the process flow of data received from a tap to determine the existence of a peak according to an embodiment of the present invention. As shown, the receiver according this embodiment of the present invention receives I and Q values at a tap at step 71. N samples of integrated correlation values (sampled values) are output to the filter 30 at step 72. According to the illustrative embodiment, N is equal to 16 and the duration of integration is 1 millisecond. The sampled I and Q values are received at the filter 30 at step 73. The sampled I and Q values are modified to have a positive value when there is a change in the sign from the prior sample value to the present sample value at step 74. The

modified I and Q values are added by the accumulator 27 at step 75. Upon

reaching N samples of I and Q value pairs, at step 76, the accumulated modified I

and Q values (variation values) are stored in memory 15 (step 77). The stored

data is processed by the FFT unit 20 at step 78 and the FFT transformed value is

5   compared against a given threshold to determine whether the maximum value is a

peak value (step 79). Then, the I and Q values are stored when the value is

maximum for phase offset of the code NCO 18 (step 80). Upon determination that

a peak exists at step 81, the navigation processor 7 calculates pseudoranges,

phase offset, etc. at step 83. When a peak does not exist at step 81, the process

10   returns to step 71 to determine a next searching frequency and code delay value

(step 82).

According to another embodiment of the present invention, the count value

from the counter 28 of Fig. 5 and count values shown in Tables I and II are used

to determine the existence of a peak at the corresponding tap. When a peak

15   exists at a tap, a count value will be close to the number of samples and of the

sampled I and Q values received. In this embodiment, the count value of a peak

tap should approach 16. Thus, a threshold of, for example, 14 can be set and if

the count value exceeds 14, decision is made that a peak exists at the present

tap. According to this embodiment, sampled I and Q values are stored in memory

20   15 for processing. The sample I and Q values of taps found to not have a count

value exceeding the threshold is determined to not have a peak and the

corresponding I and Q sampled values are not stored in memory 15. These I and

Q sampled values are not used for the acquisition operation and they are

discarded.

Fig. 10 shows the exemplary process flow according to this embodiment. As shown, the receiver receives I and Q values of a tap at step 91. N samples of integrated correlation values (sampled values) output to the filter 30. The sampled I and Q values are received at the filter 30 at step 93. The sampled I and Q values are modified to have a positive value when there is a change in the sign from the prior sample value to the present sample value at step 94. The modified I and Q values are added at the accumulator 27 at step 95. Upon reaching N samples of I and Q value pairs, at step 96, the counter value is compared against a preset threshold in logic 29 at step 97. If the count value equals or exceeds the preset threshold, the tap in question is considered a tap which potentially has a peak. In such instance, the sampled I and Q values are stored in memory 15 (step 92). The stored data is processed by the FFT unit 20 at step 78 and the FFT transformed value is compared against a given peak threshold to determine whether a peak exists at the tap (step 99). Upon determination that a peak exists at step 110, post processing to calculate pseudoranges, phase offset, etc. is performed at step 120. When a peak does not exist at step 110, the process is returned to step 91 to determine a next searching frequency and a code delay value (step 130).

Fig. 11 shows the exemplary process flow according to this embodiment. As shown, the receiver according this embodiment of the present invention receives I and Q values at a tap at step 211. N samples of integrated correlation values (sampled values) are output to the filter 15 at step 212. According to the

20

illustrative embodiment, N is equal to 16 and the duration of integration is 1

millisecond. The sampled I and Q values are received at the filter 30 at step 213.

The sampled I and Q values are modified to have a positive value when there is a

change in the sign from the prior sample value to the present sample value at step

214. The modified I and Q values are added by the accumulator 27 at step 215.

Upon reaching N samples of I and Q value pairs, at step 216, the counter value is

compared against a preset threshold in logic 29 at step 217. If the count value

equals or exceeds the preset threshold, the tap in question is considered a tap

which potentially has a peak. In such instance, the accumulated I and Q values

are stored in memory 15 (step 218). The stored data is processed by the FFT unit

20 at step 219 and the FFT transformed value is compared against a given peak

threshold to determine whether a peak exists at the tap (step 220). And then,

store I and Q values when the value is maximum for phase offset of the code

NCO 18 (step 221). Upon determination that a peak exists at step 222, post

processing to calculate pseudoranges, phase offset, etc. is performed at step 223.

When a peak does not exist at step 222, determine a next searching frequency

and a code delay value (step 224), and return to the step 211.

According to an alternative embodiment of the present invention, using the

filter 30 and the counter 28 as described above, the count value is used to

determine the existence of a potential peak at the tap in question. Upon

determination that the tap is a potential peak, instead of storing the sampled I and

Q values as in the prior embodiment, the variation values (I' + Q') are stored in the

memory 15. The stored data is then processed by the FFT unit 20 to determine

whether a peak exists at the tap. According to this embodiment, the sampled I

and Q values and variation values (I' + Q') of taps determined as not have a

potential peek are not stored in memory 15 and these date are not processed.

The memory 15 is a semiconductor memory, preferably one of a SRAM and

5 DRAM.

To further reduce the dataset to be stored in memory 15, the sampled I and

Q values can be reduced by multiplying with a fraction, such as ½, ¼, etc., prior to

their processing by the filter 15. The multiplier/shifter (not shown) can be

implemented before the values are entered into the accumulator 27 of Fig. 4.

10 Table II shows the sampled I and Q values, the fractional modified I and Q values,

the variation values (I ½ + Q ½), and count values of a tap having a peak.

-	I (same phase sample value)	Q (quadrature phase sample value)	I' /2 comparison value	Q'/2 comparison value	I' /2 + Q' /2	Variation value (sign bit value of (I' /2 + Q' /2))
1	11000	389	-5500	-194.5	-5694.5	1

Table III.

Fig. 12 is a graph showing plots of the fractional variation values extracted from Tables I to III for a non-peak tap (Table 1) and a peak tap (Table III). It can be seen that the peak tap trend is a cluster well away from the zero axis and the non-peak tap trend have values which swing in different directions around the zero axis.

It is readily appreciated by one ordinary skilled in the art that although the embodiments of the filter of the present invention are shown and described with circuit components, the filter can be implemented by software or by use of a storage device having stored codes executable by a processor, and upon execution of the codes, the filtering functions as above described are implemented. The storage device is preferably one of a flash memory and a ROM.

Although illustrative embodiments of the present invention have been described herein with reference to the accompanying drawings, it is to be understood that the invention is not limited to those precise embodiments, and that various other changes and modifications may be affected therein by one skilled in the art without departing from the scope or spirit of the invention.
